ملخص البحث

تم دراسة تأثير حدوث التحويل الجيني الذي يحدث أثناء الانقسام الميوزي لجموعة من الطفرات الواقعة داخل الجين ب<sup>2</sup> والذي يتحكم في تكوين لسون الجراثيم في القطر الاسكى أسكوبولوس امرسس على الاختلافات الناتجة داخل الجين . انتخاب وتحليل الاسكيات التي تظهر انحرال مابعد الميوزي ( الانحرال الغير متساوي ٥ : ٢ ) وذلك باستخدام طفرة تقع في وسط الهجين وهذه الانحرالات تعكس تكوين ج د ن هجين من النوع الغير متساوي شاملا جميع الطفرات المدروسة والموجودة في صورة غير متناظرة أظهر أن كل أنواع الاتصالات بين الطفرات المدروسة يمكن الحصول عليها وذلك عبر التحويل الجيني الذي يحدث أثناء الانقسام الميوزي وذلك بتكرارات عالية . وأن عملية الاصلاح لا ج د ن الهجين المعقد الذي تم تكوينه يمكن أن يكون له قيمة شميرات هامة . مثال . أن هذه الميكانيكية تكون ذات تأثير مطفر للأثر على استبدال العديد من النيكلويدات في خطوة واحدة . وكذلك يمكن لها قيمة الميكانيكية تشير مصدر بعض صور التعدد الجيني في عائلات الهجائن المصنفة في الكائنات المصنفة النواة .

## ABSTRACT

The effect of meiotic gene conversion of mutations located in the gene  $b_2$ , which controls spore pigmentation in the fungus Ascobolus immersus, on intragenic variability has been studied. Selection and analysis of asci showing postmeiotic segregation (5:3 non Mendelian segregation) at the level of an intermediate mutant site reflect asymmetric hybrid DNA formation. The hybrid DNA covering many heterozygous mutant sites, through the induction of meiotic gene conversion, gives all possible combinations between them. The in vivo processing of such complex heteroduplexes has many interesting implications. It offers a mutational mechanism capable of altering several nucleotides in a single step. It can also explain some of the genetic polymorphism in eukaryotic multigene families.

## INTRODUCTION

Gene conversion may be defined as a unidirectional transfer of genetic information from one DNA duplex to another. At the molecular level, the initiation event of gene conversion is the hybrid DNA (h-DNA) formation (Holliday, 1964; Meselson and Radding, 1975). Hybrid DNA that is present on only one chromatid of the two interacting chromatids is called asymmetric h-DNA, while that which covers the same region of the two chromatids is called symmetric h-DNA. In mutant x wild-type crosses, the formation of h-DNA at the mutation site during the interaction between homologous chromatids, which leads to genetic recombination, seems to be a reasonable explanation for the observed non-Mendelian segregations (NMS); Pukkila, 1977.

The fungus Ascobolus immersus is an excellent organism for studying recombination, since more than 20 genes involved in spore pigmentation have been defined. In Ascobolus octosporous asci are composed of four pairs of sister spores, each pair corresponding to one meiotic product. Hence, the occurrence of NMS of 5:3, aberrant 4:4 and 6:2 types can be easily detected. The 5:3 and aberrant 4:4

NMS reflect that the mismatch formed in h-DNA is not corrected and that the mutant and wild-type alleles segregate only at postmeiotic mitosis. The 6:2 NMS indicate that the mismatch formed in h-DNA is recognized and corrected leading to the transfer of a wild-type chromatid to a mutant or vice-versa. This hypothesis is supported by findings in Ascobolus (Leblon and Paquette, 1978) and in Sordaria (Yu-Sun et al., 1977).

The present study has been carried out with crosses involving up to six heterozygous sites in the b<sub>2</sub> gene. Selection for asymmetric h-DNA formation events was carried at the level of an intermediate mutant site which gives rise to all types of NMS, then the fate of h-DNA covering the flanking heterozygous sites was detected. Such in vivo processing of these complex heteroduplexes has many interesting implications as a natural source of considerable genetic diversity.

## MATERIAL AND METHODS

**Culture media:** Details of culturing conditions have been reported previously by Paquette and Rossignol (1978).

**Mutants:** The mutants used in the present study belong to stock 28 of Ascobolus immersus, and bear the CV<sub>2</sub>A modifier allele of the b<sub>2</sub> gene (Girard and Rossignol, 1974). The origin and the phenotype of these mutants are indicated in Figure 1. Three other genetic markers were used, vag<sub>8</sub> (mycelial growth), rnd<sub>1,2</sub> (round ascospore shape) and mt (mating type). They are unlinked to the b<sub>2</sub> gene (Nicolas et al., 1981).

**Nature of Mutants:** The frameshift mutation F<sub>0</sub>, F<sub>16</sub>, E<sub>2</sub> and E<sub>1</sub> lying in region F and E are assumed to correspond to small additions

or deletions of nucleotides (Leblon and Paquette, 1978). This assumption is based on the specificity of ICR<sub>170</sub> mutagen demonstrated in both Ascobolus and Sordaria (Leblon, 1972; and Yu-Sun et al., 1977) and in Saccharomyces cerevisiae (Donahue et al., 1981). By extension the double frameshift mutants F<sub>0</sub>F<sub>16</sub> and E<sub>2</sub>E<sub>1</sub> are assumed to correspond to (+1,-1) changes when compared with the wild-type sequence (Leblon and Paquette, 1978). The C<sub>234</sub> mutation corresponds to a deletion in the middle part of the b<sub>2</sub> gene (Hamza et al., 1987). X<sub>15</sub> is a type C mutant (gives both meiotic and postmeiotic segregations) and corresponds probably to a base pair substitution (Rossignol et al., 1979).

Multi mutant strain construction: The two double mutants F<sub>0</sub>F<sub>16</sub> and E<sub>2</sub>E<sub>1</sub> were constructed separately. Strains with a single mutant site give a white spore phenotype, while the two double mutants F<sub>0</sub>F<sub>16</sub> and E<sub>2</sub>E<sub>1</sub> have a pseudo wild-type phenotype and were obtained by crossing m<sub>1</sub> (F<sub>0</sub> or E<sub>2</sub>) by m<sub>2</sub> (F<sub>16</sub> or E<sub>1</sub>) and by screening for 2 coloured: 6 white spore asci among the progeny of these crosses which give essentially 8 white spore asci. The triple mutant F<sub>0</sub>F<sub>16</sub>X<sub>15</sub> was obtained by crossing F<sub>0</sub>F<sub>16</sub> by X<sub>15</sub> and screening for 3 coloured: 5 white (3C:5W) asci. The white spore of the mixed pair was then crossed by the wild-type. Among the progeny of the latter cross, 3C:5W and 5C:3W asci were isolated and the coloured spore of the mixed pair was then crossed by F<sub>0</sub>. The existence of coloured spores with a F<sub>0</sub>F<sub>16</sub> genotype was thus determined, indicating that the parental white spore was actually F<sub>0</sub>F<sub>16</sub>X<sub>15</sub>.

The F<sub>0</sub>F<sub>16</sub>X<sub>15</sub>E<sub>2</sub>E<sub>1</sub> strain was obtained by crossing F<sub>0</sub>F<sub>16</sub>X<sub>15</sub> by E<sub>2</sub>E<sub>1</sub> and screening for 3c:5w and 5c:3w spored asci. The white spore of the mixed pair was then crossed by F<sub>0</sub> and E<sub>1</sub>, respectively. The existence of coloured spores with a F<sub>0</sub>F<sub>16</sub> genotype in the cross of the white spore by F<sub>0</sub> as well as the existence of coloured spores with a E<sub>2</sub>E<sub>1</sub> genotype in the cross of the same white spore by E<sub>1</sub> indicate that the parental white spore was actually F<sub>0</sub>F<sub>16</sub>X<sub>15</sub>E<sub>2</sub>E<sub>1</sub>.

Fig. 1. Map of the  $b_2$  mutants used. Regions F and E correspond to regions in which several frame-shift mutations belonging to the same group of intragenic suppression are located (Leblon and Paquette, 1973).

Above the line: double site mutants with a pseudo-wild-type phenotype; under the line, mutants with a white spore phenotype. F<sub>0</sub> and E<sub>1</sub> were isolated by ICR 170 mutagenesis. F<sub>16</sub>, E<sub>2</sub> and F<sub>1</sub> were isolated by EMS mutagenesis. X<sub>15</sub> was induced by X rays. G<sub>1</sub> and G<sub>234</sub> are spontaneous mutations.

Testing the impact of gene conversion upon the intragenic variability: The effect of gene conversion upon the intragenic variability was tested in two different types of crosses. A set of wild-type and G<sub>234</sub> strains were used. All these strains were obtained from crosses between wild-type and G<sub>234</sub>.

The multimitation strain F<sub>0</sub>F<sub>16</sub> X<sub>15</sub> E<sub>2</sub>E<sub>1</sub> was crossed by each test strain (wild-type or G<sub>234</sub>) and a sample of 1000 asci was counted in each cross. Then a sample of 5c:3w asci was analysed. The sister spores of each pair were determined by the use of the supplementary markers mt, rnd and vag. That the white spores are X<sub>15</sub> genotype was confirmed by crossing them by X<sub>15</sub> tester and the observation of no recombinant coloured spores in the progeny. The genotype of the white spore for F<sub>0</sub>F<sub>16</sub> and E<sub>2</sub>E<sub>1</sub> can be inferred from the genotype of the sister coloured spore. The spore should have the same genotype since it is known that the F<sub>0</sub>F<sub>16</sub> and E<sub>2</sub>E<sub>1</sub> markers used give no post meiotic segregations (Rossignol *et al.*, 1979).

The genotype of coloured spores for F<sub>0</sub>F<sub>16</sub>, E<sub>2</sub>E<sub>1</sub> and G<sub>234</sub> was determined by crossing the coloured spore with F<sub>1</sub> and G<sub>1</sub> (Hamza *et al.*, 1987). The distinction between E<sub>2</sub>E<sub>1</sub>, and G<sub>234</sub> was inferred from pink (E<sub>2</sub>E<sub>1</sub>) versus brown (G<sub>234</sub>) spore phenotype.

## RESULTS AND DISCUSSION

In the two sets of the crosses F<sub>0</sub>F<sub>16</sub>X<sub>15</sub>E<sub>2</sub>E<sub>1</sub> with wild-type and G<sub>234</sub>, the NMS pattern of the X<sub>15</sub> mutation was established. The results were compared for the individual classes of NMS asci 6C:2W, 5C:3W and aberrant 4C:4W (Table 1). Statistical analysis showed that the frequency of 6C:2W asci is significantly higher in crosses with G<sub>234</sub> than with wild-type. In Table 1, the absolute frequencies of aberrant 4C:4W were corrected according to, (Paquette, 1978),

Table (1): Conversion pattern of  $X_{15}$  mutants in crosses of  $F_0F_{16}X_{15}E_2E_1$  with wild-type and with the deletion  $G_{234}$ .

| Cross                   | N    | 6c : 2w | 5c : 3w | ab. 4c:4w |
|-------------------------|------|---------|---------|-----------|
| $F_0F_{16}X_{15}E_2E_1$ | 6000 | 103     | 160     | 31 (46.5) |
| + + + + +               |      |         |         | *         |
| Freq. / 1000            |      | 17.2    | 26.7    | 5.2 (7.8) |
| $F_0F_{16}X_{15}E_2E_1$ | 5000 | 158     | 102     | 12 (18)   |
| + + + $G_{234}$         |      |         |         | *         |
| Freq. / 1000            |      | 31.6    | 20.4    | 2.4 (3.6) |

N : number of total asci observed.

ab: aberrant, in parentheses, estimated number of aberrant 4 : 4 ascic are given.. \*

\* different is significant at .05 level.

because only 2/3 of these events are observed. The results are in agreement with the previous observations obtained by Hamza *et al.* (1987). The excess of 6c:2w asci in crosses with G<sub>234</sub> is at the expense of the 5c:3w asci because G<sub>234</sub> imposes its NMS pattern on the closely linked mutations and gives preferential conversion toward the donor strand which is G<sub>234</sub> in this case (Hamza *et al.*, 1986). The decrease in aberrant 4:4 NMS frequency in crosses with G<sub>234</sub> is also the result of the fact that G<sub>234</sub> blocks the propagation of the symmetrical h-DNA at its border toward the high conversion end of the b<sub>2</sub> gene (Hamza *et al.*, 1981).

**Ascus Analysis:** Samples of intact asci with 4 oval : 4 round ascospores were analysed in each series of crosses. A total of 45 and 38 asci of the type (5c:3w) were analysed in the progeny of the crosses F<sub>0</sub>F<sub>16</sub>X<sub>15</sub>E<sub>2</sub>E<sub>1</sub> with wild-type and G<sub>234</sub>, respectively. Both coloured and mixed pairs of spores were analysed. The genotype of pairs of white spores was assumed to be F<sub>0</sub>F<sub>16</sub>X<sub>15</sub>E<sub>2</sub>E<sub>1</sub>.

The analysis showed that in crosses with wild-type, 15 types of asci can be detected while in crosses with G<sub>234</sub> only 9 types were found (Fig. 2, and Table 2). In all the asci tested X<sub>15</sub> was found to segregate postmeiotically giving rise to 5c:3w asci. In crosses with wild-type, 7 types of asci showed a Mendelian segregation of the double mutant F<sub>0</sub>F<sub>16</sub>, 4 types of asci showed a conversion of F<sub>0</sub>F<sub>16</sub> to wild-type and 4 types showed a conversion to mutant. While in crosses with G<sub>234</sub>, only 3 types of asci showed a Mendelian segregation of F<sub>0</sub>F<sub>16</sub>, 3 a conversion to wild type and also 3 types showed a conversion to mutant. In all types of asci, segregation of E<sub>2</sub>E<sub>1</sub> was observed (Fig. 2). At the DNA strand level, all possible combinations of F<sub>0</sub>F<sub>16</sub>, X<sub>15</sub>, E<sub>2</sub>E<sub>1</sub> and their wild type alleles were observed in both crosses with wild-type and G<sub>234</sub>. The frequency of different combinations ranged from 3.9-28.3% of postmeiotic segregation events in crosses with wild-type and from 2.0-43.4% in crosses with G<sub>234</sub> (Table 3).

Hybrid DNA formation in the b<sub>2</sub> gene was found to be polar with a preferential initiation region toward the high conversion end to the F region (Hamza et al., 1981). The extension of h-DNA in the b<sub>2</sub> gene was argued by Rossignol and Haedens (1980). These facts support the assumption that when selection for h-DNA formation at X<sub>15</sub> level was made, the great majority of these events cover both F<sub>0</sub>F<sub>15</sub> and E<sub>2</sub>E<sub>1</sub> sites. Previous studies in Ascobolus showed that h-DNA is the obligatory intermediate of gene conversion and confirmed that independent mismatch corrections appear along the same h-DNA tract in the b<sub>2</sub> gene (Kalogeropoulos and Rossignol, 1980). In the present study experiments were performed using mutations which have different conversional pathways (Hasting et al., 1980; Hamza et al., 1986).

The X<sub>15</sub> mutation was used to detect the meiotic events where h-DNA was formed and persisted. The 5c:3w asci reflect mainly the asymmetrical h-DNA formation with F<sub>0</sub>F<sub>15</sub>X<sub>15</sub>E<sub>2</sub>E<sub>1</sub> as the recipient DNA duplex. Analysis of 5c:3w asci led to the following conclusions:

- 1- all possible combinations between F<sub>0</sub>F<sub>15</sub>, X<sub>15</sub> and E<sub>2</sub>E<sub>1</sub> were observed.
- 2- The detection of these events in asci showing NMS of X<sub>15</sub> argued for a h-DNA formation followed by mismatch correction leading to either conversion or restoration of the mutant sites implicated in the h-DNA stretch.
- 3- The absence of some types of asci when crosses with wild-type and G<sub>23a</sub> are compared is in agreement with the properties of the known conversional pathways.

The present results as a whole show the impact of gene conversion which occurs via h-DNA formation and following mismatch correction on intragenic variability. Previous studies showed that heteroduplexes can be formed in vivo by DNA strand exchange between partial

homologous but not identical sequences (Radding, 1978). Heteroduplexes can be prepared in vitro, transformed into living cells and their in vivo correction can then be studied (Dohet et al., 1985). These studies have been carried out with simple heteroduplexes carrying one or a few nucleotide mismatches. Little is known about the correction of more complex structures involving many noncomplementary nucleotides, this mechanism could be capable of generating considerable diversity. At the same time this idea can explain some of the polymorphism in the eukaryotic multigene families. Correction of complex heteroduplexes may be used as a practical means of engineering genetic variants. One of its interesting characteristics is that all features of the primary structure common to both parents are conserved in the variants.

In higher eukaryotes, many sequences are only partially homologous and differ in many nucleotides. It has been often postulated that they can undergo crossing over and gene conversion due to their partial homology. If h-DNA is involved in any of these genetic exchanges, it must be in the form of complex heteroduplexes. The processing of these complex heteroduplexes has two interesting implications:

- 1- It may be a source of considerable genetic diversity. At least some variations could be attributed to gene conversion.
- 2- The correction of complex heteroduplexes offer a mutational mechanism capable of altering several nucleotides (amino acids) in a single step in different sites of DNA duplex (polypeptide chain). Such mechanisms can have important evolutionary significance.
